

[Frame 4] The bearer opens. This is the first RLC PDU (protocol data unit) of the capture, and it sets up everything that follows. Radio Link Control in Acknowledged Mode (AM) is the retransmission layer of the 5G radio stack: it numbers what it sends, chops it to fit whatever the scheduler grants, and refuses to let anything go missing.

Read the header fields left to right:

- SN=0 — the first sequence number on this transmitting entity. RLC counts *SDUs* — service data units, the PDCP packets handed down to it — not bytes and not transmissions.
- SI = "all bytes of an RLC SDU" (the 2-bit Segmentation Info field, value 0) — nothing was split; one PDCP packet, one PDU.
- P = "status report is requested" — the poll bit. It obliges the peer to send a STATUS PDU back.

This entity is **SRB 1**, the signaling radio bearer: the packet trace shows bearer type SRB, bearer id 1, logical-channel ID 1, and a 12-bit sequence number. The SDU is an RRCSetupComplete with an initial NAS Registration Request inside. The PDU is 108 bytes — a 2-byte AM header plus a 106-byte SDU.

[Frame 5] The first acknowledgment, 0.8 ms later. A STATUS PDU is RLC's only control message, and it is tiny — 3 bytes on the wire. ACK_SN=1 does not mean "SDU 1 arrived"; it means "*the next SDU I am still waiting for is number 1*", so everything below 1 — that is, SN 0 from frame 4 — is safely in. E1=0 says no NACK block follows — a NACK, or negative acknowledgment, is how a receiver names a specific sequence number it never got — so nothing is missing.

Worth fixing in your head now: **there are no NACKs anywhere in this capture**. Every STATUS PDU you are about to see is a pure cumulative acknowledgment.

[Frame 7] The downlink has its own counter. The gNB now sends *its* SN 0. That is not a repeat of frame 4 — an AM bearer is two independent transmitting entities, one per direction, each with its own sequence-number space, its own poll timer, and its own retransmission buffer. This one carries an RRC DLInformationTransfer wrapping a NAS Authentication Request.

[Frame 8] Same acknowledgment, fourteen times slower. ACK_SN=1 confirms the downlink SN 0 of frame 7 — but it arrives 11.2 ms after the poll, where the gNB answered frame 4 in 0.8 ms. The asymmetry is not RLC's doing: the gNB schedules its own downlink instantly, while the UE must be granted uplink airtime before it can transmit anything at all, even 3 bytes. The pattern holds for the whole session — every downlink status lands within 0.8 ms, every uplink status takes 10 to 19 ms.

[Frame 9] Uplink SN=1 , poll set — the NAS Authentication Response. Signaling is bursty and arrives one message at a time, so on this bearer nearly every data PDU is also the last thing in the transmit buffer, which is precisely the condition that makes RLC set the poll bit (TS 38.322 §5.3.3.2).

[Frame 10] ACK_SN=2 : uplink SN 0 and 1 are both delivered. The transmitter can now drop them from its retransmission buffer.

[Frame 11] Downlink SN=1 — a NAS Security Mode Command inside a DLInformationTransfer. From here the NAS payloads are ciphered with keys this capture does not carry, so the inner detail goes dark; the RLC layer, which never sees plaintext anyway, carries on exactly the same.

[Frame 12.1] Two RLC PDUs, one radio transmission. This frame is a single MAC transport block carrying *both* a 3-byte STATUS PDU and an 85-byte data PDU on the same logical channel. The status half comes first: ACK_SN=2 clears the downlink SN 0 and 1.

Piggybacking control onto a data grant is the normal case, not an optimisation – RLC hands MAC whatever it has, and MAC packs the transport block. The diagram splits the two PDUs into separate arrows so each can be read on its own.

[Frame 12.2] The data half of the same transport block:
uplink SN=2, poll set, an 83-byte SDU carrying a ciphered
NAS message.

[Frame 13] ACK_SN=3 – uplink SN 0 through 2 acknowledged.

[Frame 14] Downlink SN=2, another DLInformationTransfer with a NAS payload.

[Frame 15.1] ACK_SN=3 clears downlink SN 0 through 2, piggybacked ahead of the data PDU below, exactly as in frame 12.

[Frame 15.2] Uplink SN=3, poll set — a 19-byte SDU.

[Frame 16] ACK_SN=4 – uplink SN 3 is in.

[Frame 17] Downlink SN=3 carries the RRC SecurityModeCommand. Access-stratum ciphering and integrity protection start after this exchange; note that RLC headers are never ciphered — the SN, SI, S0 and poll bit stay in the clear so the peer's ARQ (automatic repeat request) machinery can work without keys. That is the whole reason this walkthrough is possible on a ciphered trace.

[Frame 18.1] ACK_SN=4 acknowledges the SecurityModeCommand just received.

[Frame 18.2] Uplink SN=4, poll set – RRC
SecurityModeComplete, an 8-byte SDU. Notice how small
signaling PDUs are: an 8-byte SDU becomes a 10-byte RLC
PDU inside a transport block with hundreds of bytes of
padding.

[Frame 19] ACK_SN=5 : uplink SN 0 through 4 delivered.
Security is now up, and the next downlink message is the one that will stretch RLC.

[Frame 20] Downlink SN=4 – RRC UECapabilityEnquiry. The answer to this is the largest signaling message on the bearer, and it is what forces the session's segmentation run.

[Frame 21.1] ACK_SN=5 clears downlink SN 0 through 4 — the enquiry above is confirmed received. The UE now has a 1667-byte capability report to send, and the grant it just got is nowhere near big enough.

[Frame 21.2] Segmentation, part 1 of 3. SI = "first segment of an RLC SDU" (value 1), and P is **not** set. Both facts follow from one rule: RLC splits an SDU only because the MAC grant is smaller than the SDU, and it polls only when the buffer is about to run dry. Here 1058 bytes are still queued, so no poll.

The PDU is 611 bytes: a 2-byte header (no S0 field is present on a first segment, because the offset is zero by definition) plus 609 bytes of the SDU. Remember 609 – it is the offset the next segment will carry.

[Frame 22] Segmentation, part 2 of 3. SI = "neither the first nor last segment" (value 3) and S0=609 – the Segment Offset, in bytes, from the start of the original SDU. That is exactly where frame 21 stopped. The header is now 4 bytes rather than 2, because a non-first segment must carry the 16-bit S0 field; 619 bytes on the wire therefore means 615 bytes of payload, covering bytes 609 through 1223.

Still no poll: more of the SDU remains.

[Frame 23] Segmentation, part 3 of 3 – and the point of the whole exercise. SI = "last segment" (value 2), S0=1224 , which is 609 + 615: the three segments tile the SDU without gap or overlap. Wireshark confirms the reassembly – 3 fragments, 1667 bytes, contributed as 609 + 615 + 443.

Two things to take away. First, **all three segments carry the same sequence number**, SN=5 – the number belongs to the SDU, and segmentation is described entirely by SI and S0 . Second, the poll bit is set only *here*, on the last segment, because only now is the buffer empty. The receiver will therefore acknowledge the SDU once, not three times.

The reassembled SDU is the RRC UECapabilityInformation.

[Frame 24] One acknowledgment for three transmissions. ACK_SN=6 – everything below SN 6 is delivered, and SN 5 counts as delivered only because all three of its segments arrived. This is the payoff of the previous three frames: ARQ state is per SDU, so a 1667-byte message costs exactly one entry in the retransmission buffer and one line in the status report, no matter how many pieces the scheduler forced it into.

[Frame 30] Downlink SN=5, poll set – a 62-byte SDU, back to ordinary one-PDU-per-message signaling.

[Frame 31.1] ACK_SN=6 clears downlink SN 5 from frame 30.

[Frame 31.2] Uplink SN=6, poll set, piggybacked in the same transport block as the status above.

[Frame 32] ACK_SN=7 — uplink SN 6 delivered. A 1.37-second pause follows while the core network works; RLC simply idles, with nothing outstanding in either direction.

[Frame 36] Uplink SN=7 after the pause, poll set — a 101-byte SDU. The sequence numbers pick up exactly where they left off: an idle AM entity keeps its state.

[Frame 37] ACK_SN=8 – uplink SN 7 delivered.

[Frame 38] The most consequential SDU on this bearer.
Downlink SN=6 is an RRC Reconfiguration, and decoded it adds a Data Radio Bearer (DRB) 1 on logical-channel ID 4, with its own RLC entity configured as:

- sn-FieldLength – size18, in both directions
- t-PollRetransmit – ms80 (uplink)
- pollPDU / pollByte – p32768 / kB750 (uplink)
- t-Reassembly – ms80 (downlink)
- t-StatusProhibit – ms30 (downlink)

That bearer is a **separate RLC entity** with its own sequence-number space — nothing it sends shares a counter with anything on this diagram. Its story is the companion data-bearer walkthrough; this remark is where it begins.

The frame matters here for a second reason too. It is the only frame in the entire capture that signals any RLC configuration at all. **SRB 1 is never configured explicitly**, so this bearer runs the default acknowledged-mode profile of TS 38.331 §9.2.1 — 12-bit SN, `t-PollRetransmit` of 45 ms. That default becomes visible, and measurable, at frames 129 and 146.

[Frame 39.1] ACK_SN=7 acknowledges the reconfiguration of frame 38 at the RLC level – delivery confirmed, though the RRC-level confirmation is the PDU immediately below.

[Frame 39.2] Uplink SN=8, poll set – RRCReconfigurationComplete.
